Abstract
Data selection is an effective approach to domain adaptation in statistical machine translation. The idea is to use language models trained on small in-domain text to select similar sentences from large general-domain corpora, which are then incorporated into the training data. Substantial gains have been demonstrated in previous works, which employ standard n-gram language models. Here, we explore the use of neural language models for data selection. We hypothesize that the continuous vector representation of words in neural language models makes them more effective than n-grams for modeling unknown word contexts, which are prevalent in general-domain text. In a comprehensive evaluation of 4 language pairs (English to German, French, Russian, Spanish), we found that neural language models are indeed viable tools for data selection: while the improvements are varied (i.e. 0.1 to 1.7 gains in BLEU), they are fast to train on small in-domain data and can sometimes substantially outperform conventional n-grams.

1 Introduction
A perennial challenge in building Statistical Machine Translation (SMT) systems is the dearth of high-quality bitext in the domain of interest. An effective and practical solution is adaptation data selection: the idea is to use language models (LMs) trained on in-domain text to select similar sentences from large general-domain corpora. The selected sentences are then incorporated into the SMT training data. Analyses have shown that this augmented data can lead to better statistical estimation or word coverage (Duh et al., 2010; Haddow and Koehn, 2012).

Although previous works in data selection (Axelrod et al., 2011; Koehn and Haddow, 2012; Yasuda et al., 2008) have shown substantial gains, we suspect that the commonly-used n-gram LMs may be sub-optimal. The small size of the in-domain text implies that a large percentage of general-domain sentences will contain words not observed in the LM training data. In fact, as many as 60% of general-domain sentences contain at least one unknown word in our experiments. Although the LM probabilities of these sentences could still be computed by resorting to back-off and other smoothing techniques, a natural question remains: will alternative, more robust LMs do better?

We hypothesize that the neural language model (Bengio et al., 2003) is a viable alternative, since its continuous vector representation of words is well-suited for modeling sentences with frequent unknown words, providing smooth probability estimates of unseen but similar contexts. Neural LMs have achieved positive results in speech recognition and SMT reranking (Schwenk et al., 2012; Mikolov et al., 2011a). To the best of our knowledge, this paper is the first work that examines neural LMs for adaptation data selection.

2 Data Selection Method
We employ the data selection method of (Axelrod et al., 2011), which builds upon (Moore and Lewis, 2010). The intuition is to select general-domain sentences that are similar to in-domain text, while being dis-similar to the average general-domain text.

To do so, one defines the score of an general-domain sentence pair \((e, f)\) as:

\[
[IN_E(e) - GEN_E(e)] + [IN_F(f) - GEN_F(f)]
\]

(1)

where \(IN_E(e)\) is the length-normalized cross-entropy of \(e\) on the English in-domain LM. \(GEN_E(e)\) is the length-normalized cross-entropy
of \( e \) on the English general-domain LM, which is built from a sub-sample of the general-domain text. Similarly, \( IN_F(f) \) and \( GEN_F(f) \) are the cross-entropies of \( f \) on Foreign-side LM. Finally, sentence pairs are ranked according to Eq. 1 and those with scores lower than some empirically-chosen threshold are added to the bitext for translation model training.

### 2.1 Neural Language Models

The four LMs used to compute Eq. 1 have conventionally been n-grams. N-grams of the form \( p(w(t)|w(t-1), w(t-2), \ldots) \) predict words by using multinomial distributions conditioned on the context \( (w(t-1), w(t-2), \ldots) \). But when the context is rare or contains unknown words, n-grams are forced to back-off to lower-order models, e.g. \( p(w(t)|w(t-1)) \). These backoffs are unfortunately very frequent in adaptation data selection.

Neural LMs, in contrast, model word probabilities using continuous vector representations. Figure 1 shows a type of neural LMs called recurrent neural networks (Mikolov et al., 2011b).\(^1\) Rather than representing context as an identity (n-gram hit-or-miss) function on \( [w(t-1), w(t-2), \ldots] \), neural LMs summarize the context by a hidden state vector \( s(t) \). This is a continuous vector of dimension \(|S|\) whose elements are predicted by the previous word \( w(t-1) \) and previous state \( s(t-1) \). This is robust to rare contexts because continuous representations enable sharing of statistical strength between similar contexts. Bengio (2009) shows that such representations are better than multinomials in alleviating sparsity issues.

\(^1\)Another major type of neural LMs are the so-called feed-forward networks (Bengio et al., 2003; Schwenk, 2007; Nakamura et al., 1990). Both types of neural LMs have seen many improvements recently, in terms of computational scalability (Le et al., 2011) and modeling power (Arisoy et al., 2012; Wu et al., 2012; Alexandrescu and Kirchhoff, 2006). We focus on recurrent networks here since there are fewer hyper-parameters and its ability to model infinite context using recursion is theoretically attractive. But we note that feed-forward networks are just as viable.

Now, given state vector \( s(t) \), we can predict the probability of the current word. Figure 1 is expressed formally in the following equations:

\[
w(t) = [w_0(t), \ldots, w_k(t), \ldots, w_{|W|}(t)]
\]

\[
w_k(t) = g \left( \sum_{j=0}^{|S|} s_j(t)V_{kj} \right)
\]

\[
s_j(t) = f \left( \sum_{i=0}^{|W|} w_i(t-1)U_{ji} + \sum_{i'=0}^{|S|} s_{i'}(t-1)A_{ji'} \right)
\]

Here, \( w(t) \) is viewed as a vector of dimension \(|W|\) (vocabulary size) where each element \( w_k(t) \) represents the probability of the \( k \)-th vocabulary item at sentence position \( t \). The function \( g(z_k) = e^{z_k}/\sum_k e^{z_k} \) is a softmax function that ensures the neural LM outputs are proper probabilities, and \( f(z) = 1/(1+e^{-z}) \) is a sigmoid activation that induces the non-linearity critical to the neural network’s expressive power. The matrices \( V, U, \) and \( A \) are trained by maximizing likelihood on training data using a ”backpropagation-through-time” method.\(^2\) Intuitively, \( U \) and \( A \) compress the context (\(|S| < |W|\)) such that contexts predictive of the same word \( w(t) \) are close together.

Since proper modeling of unknown contexts is important in our problem, training text for both n-gram and neural LM is pre-processed by converting all low-frequency words in the training data (frequency=1 in our case) to a special ”unknown” token. This is used only in Eq. 1 for selecting general-domain sentences; these words retain their surface forms in the SMT train pipeline.

### 3 Experiment Setup

We experimented with four language pairs in the WIT\(^3\) corpus (Cettolo et al., 2012), with English (en) as source and German (de), Spanish (es), French (fr), Russian (ru) as target. This is the in-domain corpus, and consists of TED Talk transcripts covering topics in technology, entertainment, and design. As general-domain corpora, we collected bitext from the WMT2013 campaign, including CommonCrawl and NewsCommentary for all 4 languages. Europarl for de/es/fr, UN for es/fr, Gigaword for fr, and Yandex for ru. The in-domain data is divided into a training set (for SMT

\(^2\)The recurrent states are unrolled for several time-steps, then stochastic gradient descent is applied.
pipeline and neural LM training), a tuning set (for MERT), a validation set (for choosing the optimal threshold in data selection), and finally a test set of 1616 sentences. Table 1 lists data statistics.

For each language pair, we built a baseline in-data SMT system trained only on in-domain data, and an all-data system using combined in-domain and general-domain data. We then built 3 systems from augmented data selected by different LMs:

- **ngram**: Data selection by 4-gram LMs with Kneser-Ney smoothing (Axelrod et al., 2011)
- **neuralnet**: Data selection by Recurrent neural LM, with the RNNLM Toolkit.
- **combine**: Data selection by interpolated LM using n-gram & neuralnet (equal weight).

All systems are built using standard settings in the Moses toolkit (GIZA++ alignment, grow-diag-final-and, lexical reordering models, and SRILM). Note that standard n-grams are used as LMs for SMT; neural LMs are only used for data selection. Multiple SMT systems are trained by thresholding on \{10k,50k,100k,500k,1M\} general-domain sentence subsets, and we empirically determine the single system for testing based on results on a separate validation set (in practice, 500k was chosen for fr and 1M for es, de, ru.).

### 4 Results

#### 4.1 LM Perplexity and Training Time

First, we measured perplexity to check the generalization ability of our neural LMs as language models. Recall that we train four LMs to compute each of the components of Eq. 1. In Table 2, we compared each of the four versions of ngram, neuralnet, and combine LMs on in-domain test sets or general-domain held-out sets. It re-affirms previous positive results (Mikolov et al., 2011a), with neuralnet outperforming ngram by 20-30% perplexity across all tasks. Also, combine slightly improves the perplexity of neuralnet.

![Perplexity Table](http://example.com/table2.png)

![Training Time Table](http://example.com/table3.png)

Second, we show that the usual concern of neural LM training time is not so critical for the in-domain data sizes used domain adaptation. The complexity of training Figure 1 is dominated by computing Eq. 3 and scales as $O(|W| \times |S|)$ in the number of tokens. Since $|W|$ can be large, one practical trick is to cluster the vocabulary so that the output dimension is reduced. Table 3 shows the training times on a 3.3GHz XeonE5 CPU by varying these two main hyper-parameters ($|S|$ and cluster size). Note that the setting $|S| = 200$ and cluster size of 100 already gives good perplexity in reasonable training time. All neural LMs in this paper use this setting, without additional tuning.

4.2 End-to-end SMT Evaluation

Table 4 shows translation results in terms of BLEU (Papineni et al., 2002), RIBES (Isozaki et al., 2010), and TER (Snover et al., 2006). We observe that all three data selection methods essentially outperform alldata and indata for all language pairs, and neuralnet tend to be the best in all metrics. E.g., BLEU improvements over ngram are in the range of 0.4 for en-de, 0.5 for en-es, 0.1 for en-fr, and 1.7 for en-ru. Although not all improvements are large in absolute terms, many are statistically significant (95% confidence).

We therefore believe that neural LMs are generally worthwhile to try for data selection, as it rarely underperform n-grams. The open question is: what can explain the significant improvements in, for example Russian, Spanish, German, but the lack thereof in French? One conjecture is that neural LMs succeeded in lowering testset out-of-vocabulary (OOV) rate, but we found that OOV reduction is similar across all selection methods.

The improvements appear to be due to better probability estimates of the translation/reordering models. We performed a diagnostic by decoding the testset using LMs trained on the same testset, while varying the translation/reordering tables with those of ngram and neuralnet; this is a kind of pseudo forced-decoding that can inform us about which table has better coverage. We found that across all language pairs, BLEU differences of translations under this diagnostic become insignificant, implying that the raw probability value is the differentiating factor between ngram and neuralnet. Manual inspection of en-de revealed that many improvements come from lexical choice in morphological variants ("meinen Sohn" vs. "mein Sohn"), segmentation changes ("baking soda" → "Backpulver" vs. "baken Soda"), and handling of unaligned words at phrase boundaries.

Finally, we measured the intersection between the sentence set selected by ngram vs neuralnet. They share 60-75% of the augmented training data. This high overlap means that ngram and neuralnet are actually not drastically different systems, and neuralnet with its slightly better selections represent an incremental improvement.6

5 Conclusions

We perform an evaluation of neural LMs for adaptation data selection, based on the hypothesis that their continuous vector representations are effective at comparing general-domain sentences, which contain frequent unknown words. Compared to conventional n-grams, we observed end-to-end translation improvements from 0.1 to 1.7 BLEU. Since neural LMs are fast to train in the small in-domain data setting and achieve equal or incrementally better results, we conclude that they are an worthwhile option to include in the arsenal of adaptation data selection techniques.

Table 4: End-to-end Translation Results. The best results are bold-faced. We also compare neural LMs to ngram using pairwise bootstrap (Koehn, 2004): "+" means statistically significant improvement and "−" means significant degradation.

6This is corroborated by another analysis: taking the union of sentences found by ngram and neuralnet gives similar BLEU scores as neuralnet.
Acknowledgments

We thank Amittai Axelrod for discussions about data selection implementation details, and an anonymous reviewer for suggesting the union idea for results analysis. K. D. would like to credit Spyros Matsoukas (personal communication, 2010) for the trick of using LM-based pseudo forced-decoding for error analysis.
